Timothée Poisot — [timothee.poisot@umontreal.ca](mailto:timothee.poisot@umontreal.ca)

NCBITaxonomy.jl is a package designed to facilitate the reconciliation and cleaning of taxonomic names, using a local copy of the NCBI taxonomic backbone (Federhen 2012, Schoch et al. 2020); The basic search functions are coupled with quality-of-life functions including case-insensitive search and custom fuzzy string matching to facilitate the amount of information that can be extracted automatically while allowing efficient manual curation and inspection of results. NCBITaxonomy.jl works with version 1.6 of the Julia programming language (Bezanson et al. 2017), and relies on the Apache Arrow format to store a local copy of the NCBI raw taxonomy files. The design of NCBITaxonomy.jl has been inspired by similar efforts, like the R package taxadb (Norman et al. 2020), which provides an offline alternative to packages like taxize (Chamberlain and Szöcs 2013).

This work is released by its authors under a CC-BY 4.0 license

Last revision: *March 2, 2023*

1 Unambiguously identifying species is a far more challenging task than it may appear. There are a vast number  
2 of reasons for this. Different databases keep different taxonomic “backbones”, *i.e.* different data structures in  
3 which names are mapped to species, and organised in a hierarchy. Not all names are unique identifiers to  
4 groups. For example, *Io* can either refer to a genus of plants from the aster family, or to a genus of molluscs; the  
5 genus *Mus* (of which the house mouse *Mus musculus* is a species), contains a sub-genus *also* named *Mus*  
6 (within which *Mus musculus* is located). Conversely, the same species can have several names, which are valid  
7 synonyms: for example, the domestic cow *Bos taurus* admits *Bos primigenius taurus* as a valid synonym. In  
8 addition to binomial names, the same species can be known by many vernacular (common) names, which are  
9 language or even region-specific: *Ovis aries*, for example, has valid English vernaculars including lamb, sheep,  
10 wild sheep, and domestic sheep.

11 In addition, taxonomic nomenclature changes regularly, with groups being split, merged, or moved to a new  
12 position in the tree of life; often, taxonomic revisions lead to these events occurring simultaneously. This is,  
13 notably, a common occurrence with viral taxonomy, each subsequent version of which can differ markedly from  
14 the last; compare, *e.g.* Lefkowitz et al. (2018) to Walker et al. (2020), where entire viral sub-trees were split,  
15 re-organized, and created within just two years. As a consequence any mapping of names to other biological  
16 entities can become outdated, and therefore invalid. These taxonomic changes have profound implications for  
17 the way we perceive biodiversity at global scales (Dikow et al. 2009), to the point where taxonomic revisions  
18 should sometimes be actively conducted to improve *e.g.* conservation outcomes (Melville et al. 2021).

19 None of these issues, were they to happen in isolation, would be very difficult to deal with. Indeed, performing  
20 the lookup for any text string in any database is a trivial operation. But to add to the complexity, one must also  
21 consider that most taxa names are at some point manually typed, which has the potential to introduce additional  
22 sources of variation in raw data; it is likely to expect that such mistakes may arise when attempting to write  
23 down the (perfectly valid) names of the bacterial isolate known as *Myxococcus*  
24 *llanfairpwllgwyngyllgogerychwyrndrobwlantysiliogogochensis*, or of the crowned slaty flycatcher  
25 *Griseotyrannus aurantioatrocristatus*. These mistakes are more likely when dealing with hyper-diverse samples  
26 (demanding to memorize more names), like plant census (Dauncey et al. 2016, Wagner 2016, Conti et al.  
27 2021); when dealing with multiple investigators with different knowledge of the taxonomy; and as a result of the  
28 estimated error in any data entry exercise, which other fields estimate at up to about 5% (Barchard and Pace  
29 2011). As a result, the first question one needs to ask when confronted with a string of character that  
30 purportedly points to a node in the tree of life is not “to which entry in the taxonomy database is it associated?”,

31 but “is there a mistake in this name that is likely to render a simple lookup invalid?”.

32 All these considerations become important when matching species names both within and across datasets. Let  
33 us consider the hypothetical species survey of riverine fishes: European chub, *Cyprinus cephalus*, *Leuciscus*  
34 *cephalus*, *Squalius cephalus*. All are the same species (*S. cephalus*), referred to as one of the vernacular  
35 (European chub) and two formerly accepted names now classified as synonyms (but still present in the  
36 literature). A simple estimate of diversity based on the user-supplied names would give  $n = 4$  species, when  
37 there is in fact only one. When the size of biodiversity datasets increases, and notably when the taxonomic  
38 scope of these datasets explodes, including organisms for which “names” are a fuzzier concept (for example,  
39 *Influenza A virus (A/Sydney/05/97-like(H3N2))* is a valid name for a common influenza strain, although one that  
40 lacks a taxonomic rank), the feasibility of manual curation decreases.

41 In this manuscript, we describe `NCBITaxonomy.jl`, a Julia package that provides advanced name matching and  
42 error handling capacities for the reconciliation of taxonomic names to the NCBI database. This package was  
43 used to facilitate the development of the *CLOVER* (Gibb et al. 2021) database of host-virus associations, by  
44 reconciling the names of viruses and mammals from four different sources, where all of the issues described  
45 above were present. More recently, it has become part of the automated curation of data for the *VIRION*  
46 (Carlson et al. 2022) database, which automatically curates an up-to-date, authoritative virome network from  
47 dozens of heterogeneous sources. We describe the core capacities of this package, and highlight how it enables  
48 safe, high-performance name reconciliation.

## 49 **Relevance and comparison to other tools**

50 `NCBITaxonomy.jl` is built around a series of

51 First, we specifically target programmatic (as opposed to command-line) based approaches, so that the  
52 functionalities of the package can be accessed as part of a larger pipeline. This differs from other tools offering  
53 access to the NCBI taxonomy, such as

Table 1: Comparison of core features of packages offering access to the NCBI taxonomic backbone. “Library”: ability to be called from code. “CLI”: ability to work as a command-line tool. “Local DB”: ability to store a copy of the database locally. “Fuzzy”: ability to perform fuzzy matching on inputs. “Case”: ability to perform case-insensitive search. “Subsets”: ability to limit the search to a subset of the raw database. “Ranks”: ability to limit the search to specific taxonomic ranks. The features of the various packages have been determined from reading their documentation.

Tool	Lang.	Library	CLI	Local					Reference
				DB	Fuzzy	Case	Subsets	Ranks	
NCBITaxonomy.jl	Julia								
taxadb	R								
rentrez	R								
Taxonkit	Python								
taxopy	Python								
NCBI-taxonomist	Python								

## Overview of functionalities

An up-to-date version of the documentation for `NCBITaxonomy.jl` can be found in the package git repository (<https://github.com/PoisotLab/NCBITaxonomy.jl>), including examples and in-line documentation of every method. The package is released under the MIT license. Contributions can be made in the form of issues (bug reports, questions, features suggestions) and pull requests.

In order to achieve good performance, the package will first retrieve the latest (as validated by its checksum) NCBI taxonomy backbone, store it locally, and pre-process it as a set of Julia data tables. By default, the taxonomy will be downloaded to the user’s home directory, which is not an ideal solution, and therefore we recommend that users set an environment variable to specify where the data will be loaded from (this path will be created if it doesn’t exist):

```
ENV["NCBITAXONOMY_PATH"] = joinpath(homedir(), "data", "NCBITaxonomy.jl")
```

Note that this location can be different for different projects, as the package is able to update the taxonomic backbone (and will indeed prompt the user to do so if the taxonomy is more than 90 days old). The package can then be checked out and installed anonymously from the central Julia repository:

```
using Pkg  
Pkg.add("NCBITaxonomy") # Downloading the files may take a long time
```

As long as the package is not re-built, the local set of tables downloaded from NCBI will not change; this way, users can re-run an analysis with a guarantee that the underlying taxonomic backbone has not changed, which is not the case when relying on API queries. In order to update the taxonomic backbone, users can call the `build` function of Julia's package manager (`]build NCBITaxonomy`), which will download the most recent version of all files.

This software note describes version `v0.3.0` of the package (we follow semantic versioning), which works on Julia 1.5 upwards. The dependencies are all resolved by the package manager at installation, and (on the user-facing side) include the `StringDistances.jl` package, allowing users to experiment with different string matching methods. As is best practices for Julia packages, a `Project.toml` file specifying compatible dependencies versions is distributed with the package. The code is covered by unit-tests (with about 98% coverage), as well as integration tests as part of the documentation (specifically, a use-case detailing how to clean data from a biodiversity survey, and a use-case aiming to reconstruct a taxonomic tree for the Lemuriformes).

## Improved name matching

Name finding, *i.e.* the matching of an arbitrary string to a taxonomic identifier, is primarily done through the `taxon` function, which admits either a unique NCBI identifier (*e.g.* `taxon(36219)` for the bogue *Boops boops*), a string (`taxon("Boops boops")`), or a data frame with a restricted list of names in order to create a name finder function (see the next section). The `taxon` method has additional arguments to perform fuzzy matching in order to catch possible typos (`taxon("Boops bops"; strict=false)`), to perform a lowercase search (useful when alphanumeric codes are part of the taxon name, like for some viruses), and to restrict the the search to a specific taxonomic rank. The `taxon` function also accepts a `preferScientificName` keyword, to prevent matching vernacular names; the use of this keyword ought to be informed by knowledge about how the data were entered.

The lowercase search can be a preferable alternative to fuzzy string matching. Consider the string `Adeno-associated virus 3b` - it has three names with equal distance (under the Levenshtein string distance function):

```
julia> similarnames("Adeno-associated virus 3b"; threshold=0.95)
3-element Vector{Pair{NCBITaxon, Float64}}:
  Adeno-associated virus - 3 (ncbi:46350) ⇒ 0.96
  Adeno-associated virus 3B (ncbi:68742) ⇒ 0.96
  Adeno-associated virus 3A (ncbi:1406223) ⇒ 0.96
```

92 Depending on the operating system (and specifically whether it is case-sensitive), either of these three names  
 93 can be returned; compare to the output of a case insensitive name search:

```
julia> taxon("Adeno-associated virus 3b"; casesensitive=false)
Adeno-associated virus 3B (ncbi:68742)
```

94 This returns the correct name.

## 95 Name matching output and error handling

96 When it succeeds, taxon will return a NCBITaxon object (made of a name string field, and an id numerical  
 97 field). That being said, the package is designed under the assumption that ambiguities should yield an error for  
 98 the user to handle. There are two such errors: NameHasNoDirectMatch (with instructions about how to possible  
 99 solve it, using the similarnames function), or a NameHasMultipleMatches (listing the possible valid matches,  
 100 and suggesting to use alternativetaxa to find the correct one). Therefore, the common way to work with the  
 101 taxon function would be to wrap it in a try/catch statement:

```
try
    taxon(name)
    # Additional operations with the matched name
catch err
    if isa(err, NameHasNoDirectMatch)
        # What to do if no match is found
    elseif isa(err, NameHasMultipleMatches)
        # What to do if there are multiple matches
```

```

else
  # What to do in case of another error that is not NCBITaxonomy specific
end
end
end

```

These functions will not demand any user input in the form of key presses (though they can be wrapped in additional code to allow it), as they are intended to run on clusters or virtual machines without supervision. The `taxon` function has good scaling using multiple threads. For convenience in rapidly getting a taxon for demonstration purposes, we also provide a string macro, whereby *e.g.* `ncbi"Procyon lotor"` will return the taxon object for the raccoon.

## Name filtering functions

As the full NCBI names table has over 3 million entries at the time of writing, we have provided a number of functions to restrict the scope of names that are searched. These are driven by the NCBI *divisions*. For example `nf = mammalfilter(true)` will return a data frame containing the names of mammals, inclusive of rodents and primates, and can be used with *e.g.* `taxon(nf, "Pan")`. This has the dual advantage of making search faster, but also of avoiding matching on names that are shared by another taxonomic group (which is not an issue with *Pan*, but is an issue with *e.g.* *Io* as mentioned in the introduction, or with the common name *Lizard*, which fuzzy-matches on the hemipteran genus *Lisarda* rather than the class *Lepidosauria*).

Note that the use of a restricted list of names can have significant performance consequences: compare, for example, the time taken to return the taxon *Pan* in the entire database, in all mammals, and in all primates:

Names list	Fuzzy matching	Time (ms)	Allocations	Memory allocated
all	no	23	34	2 KiB
	yes	105	2580	25 MiB
mammalfilter(true)	no	0.55	32	2 KiB
	yes	1.9	551	286 KiB
primatefilter()	no	0.15	33	2 KiB
	yes	0.3	92	27 KiB

117 Clearly, the optimal search strategy is to (i) rely on name filters to ensure that search are conducted within the  
118 appropriate NCBI division, and (ii) only rely on fuzzy matching when the strict or lowercase match fails to  
119 return a name, as fuzzy matching can result in order of magnitude more run time and memory footprint. These  
120 numbers were obtained on a single Intel i7-8665U CPU (@ 1.90GHz). Using "chimpanzees" as the search  
121 string (one of the NCBI recognized vernaculars for *Pan*) gave qualitatively similar results, suggesting that there  
122 is no performance cost associated with working with synonyms or vernacular input data.

## 123 **Quality of life functions**

124 In order to facilitate working with names, we provide the authority function (gives the full taxonomic  
125 authority for a name), synonyms (to get alternative valid names), vernacular (for English common names), and  
126 rank (for the taxonomic rank). These functions are not used in name matching, but are often useful in the  
127 post-processing of results.

## 128 **Taxonomic lineages navigation**

129 The children function will return all nodes that are directly descended from a taxon; the descendants function  
130 will recursively apply this function to all descendants of these nodes, until only terminal leaves are reached. The  
131 parent function is an “upwards” equivalent, giving the taxon from which a taxon descends; the lineage  
132 function chains calls to parent until either taxon(1) (the taxonomy root) or an arbitrary ancestor is reached.

133 The taxonomicdistance function (and its in-place equivalent, taxonomicdistance!, which uses  
134 memory-efficient re-allocation if the user needs to change the distance between taxonomic ranks) uses the  
135 Shimatani (2001) approach to reconstruct a matrix of distances based on taxonomy, which can serve as a rough  
136 proxy when no phylogenies are available. This allows coarse estimations of taxonomic diversity based on  
137 species lists. The default distance between taxonomic levels is as in Shimatani (2001) (*i.e.* species have a  
138 distance of 0, genus of 1, family of 2, sub-classes of 3, and everything else 4), but specific scores can be passed  
139 for *any* taxonomic level known to the NCBI name table.

## Conclusion

NCBITaxonomy.jl enables rapid, taxonomically-restricted, adaptive matching for taxonomic names. By implementing various combinations of search strategies, it allows users to (i) optimize the speed of their queries and (ii) avoid usual caveats of simple string matching. Through explicit exceptions, it allows to write code that will handle the possible edge cases that cannot be solved automatically in a way that does not interrupt execution, or requires manual input by the user. Given the breadth of the NCBI taxonomy database, NCBITaxonomy.jl is particularly suited to the name cleaning of large datasets of names.
